

Not So Science Fiction After All, the Internet Could Out-Evolve Humanity

Beware the digital evolution. Credit: Pixabay, CC BY

Living things accumulate and reproduce information. That's really the driving principle behind life, and behind evolution.

But humans have invented a new method of accumulating and reproducing [information](#). It's [digital information](#), and it's growing at an [astonishing speed](#). The number of people [using the internet](#) is growing, as are the [devices connected to it](#) through the Internet of Things.

[Related Article: The Internet of the Future \(What It Will Become\) – Rap News](#)

Digital information can copy itself perfectly, increases in copy number with every download or view, can be modified (mutated), or combined to generate novel information packets. And it can be expressed through [artificial intelligence](#). These are characteristics similar to living things. So we should probably start thinking about [digital technology](#) as being like an organism that can evolve.

Digital information replicates with virtually no [energy costs](#), and has rapid generation times. Artificial intelligence can beat us in chess and on game shows. What's more, it's faster than us, smarter than us in some arenas, and is already in charge of activities that are too complex for us to do efficiently.

To biologists, that sounds like the digital world might be able to out-compete us, as we argue in a [paper](#) published in *Trends in Ecology & Evolution*.

Information growth

Any newly evolving entity can cause upheavals for life on Earth. In fact, all the major [evolutionary transitions](#) in the history of life have come about via changes to information storage and transmission.

And the digital revolution has certainly changed the way information is stored and transmitted.

The current storage capacity of the internet is [approaching](#) 10^{24} bytes and is growing at [30% to 40% per year](#), showing no signs of slowing down.

In the 3.7 billion years since life began, [information in living things](#) (DNA) has reached the equivalent of about 10^{37} bytes. Digital information will grow to this size in 100

years. That's an evolutionary eye-blink.

Winners and losers

During each evolutionary transition, there have been winners and losers. And we need to start asking if the digital transition poses a danger to humanity. We do have the advantage of hindsight to answer this question.

We know that each of earth's evolutionary transitions essentially resulted in the enslavement of the old information carriers. RNA was the original carrier of information. When DNA came along, the role of RNA was relegated to simply relaying messages from DNA to the cell.

When complex cells arose, they subsumed simpler bacterial cells. These became power generators (mitochondria) or solar panels (chloroplasts), serving the needs of the new cell types.

The next transition resulted in organisms with multiple cells. Most of these cells did not pass their information to the next generation, but existed simply to support those few cells that did.

The development of nervous systems that collected information from the environment provided huge advantages for animals. This activity reached its peak in human societies, with transmission of information between generations, via language and culture.

This allowed humans to dominate the planet, such that we have triggered a new geological epoch, the [Anthropocene](#).
